

--The invention relates to a decoder for decoding an encoded digital signal that has been obtained by encoding a wideband digital signal of a specific sampling frequency F_s , for example a digital audio signal, in an encoder; and more particularly to a decoder for such an encoded digital signal comprising consecutive frames, where each frame comprises a plurality of information packets, each information packet comprising N bits, N being larger than 1. A frame comprises at least a first frame portion including synchronization information. The decoder has an input for receiving the encoded digital signal, ~~the decoder~~ and is adapted to convert the encoded digital signal into a replica of the wideband digital signal. The decoder has an output to supply the replica of the wideband digital signal. The invention also relates to a receiver comprising such a decoder. --

1 --SUMMARY OF THE INVENTION

2 An object of the invention is to provide an encoder
3 which can economically decode a digital signal having frames
4 divided into differing numbers of packets.

5 Another object of the invention is to decode a digital
6 signal so as to obtain a replica of the wideband signal.

7 According to the invention, the decoder provides a
8 faithful replica of the original wideband signal when the
9 number B of information packets in one frame has a relation to
10 a value P, such that, if P in the formula

11 ~~BR~~
~~t40~~
$$P = \frac{BR}{N} \cdot X \cdot \frac{n_s}{F_s}$$

12 is an integer, where BR is the bitrate of the encoded digital
13 signal and n_s is the number of samples of the wideband digital
14 signal whose corresponding information in the encoded digital
15 signal is included in one frame of the encoded digital signal,
16 the number B of information packets in one frame is P; and if P
17 is not an integer, the number B of information packets in a
18 number of frames is P', where P' is the next lower integer
19 below
20 ~~following~~
21 ~~A~~, and the number of information packets in the other
22 frames is equal to P'+1 so as to exactly comply with the
23 requirement that the average framerate of the encoded digital
24 signal is substantially equal to F_s/n_s .

25 The purpose of dividing the frames into B information
26 packets is that, for a wide-band digital signal of a sampling
27 frequency F_s , the average frame rate of the encoded digital
28 signal received is now such that the duration of a frame in the
digital signal corresponds to the duration occupied by n_s .

1 samples of the wide-band signal.

2 Preferably, the first frame portion further contains
3 information related to the number of information packets in a
4 frame. In a frame comprising B information packets this
5 information may be equal to the value B . This means that this
6 information corresponds to P' for frames comprising P'
7 information packets and to $P'+1$ for frames comprising $P'+1$
8 information packets. Another possibility is that this
9 information corresponds to P' for all frames, regardless of
10 whether a frame comprises P' or $P'+1$ information packets. The
11 additionally inserted $(P'+1)$ th information packet may comprise
12 for example merely "zeros". In that case this information
13 packet does not contain any useful information. Of course, the
14 additional information packet may also be filled with useful
15 information.

16 The first frame portion may further comprise system
17 information. This may include the sample frequency F_s of the
18 wide-band digital signal applied to the transmitter, copy-
19 protection codes, the type of wide-band digital signal applied
20 to the transmitter, such as a stereo-audio signal or a mono-
21 audio signal, or a digital signal comprising two substantially
22 independent audio signals. However, other system information is
23 also possible, such as the bitrate, as will become apparent
24 hereinafter. Including the system information makes it possible
25 for the receiver and thus the decoder in the receiver to be
26 flexible and enables the received digital signal to be
27 correctly reconverted into the wide-band digital signal.

28 The frames may comprise second and the third frame
29 portions. Those frame portions contain other signal
30 information, such as allocation information, quantized samples

1 and scale factor information. Upon encoding, the wideband
2 digital signal can be split up so as to generate a number of M
3 subsignals, M being larger than 1. Those subsignals are
4 quantised so as to obtain quantized subsignals. For this
5 purpose an arbitrary encoding, such as a transform coding or a
6 subband coding, may be used. At the receiving end it is then
7 necessary to apply an inverse encoding to recover the wideband
8 digital signal.

9
10 In order to make the signal information available for
11 decoding, the decoder is provided with retrieval means for
12 retrieving the allocation information, the quantized samples
and the scale factor information.

13 Preferably, the allocation information is inserted in
14 a frame before the samples. This allocation information is
15 needed to enable the continuous serial bit stream of the
16 samples in the third frame portion to be subdivided into the
17 various individual quantized samples of the correct number of
18 bits at the receiving end. An adaptive bit allocation are
19 described inter alia in the publication "Low bit-rate coding of
20 high quality audio signals. An introduction to the MASCAM
21 system" by G. Theile et al, EBU Technical Review, No. 230
(August 1988). Inserting the allocation information in a frame
22 before the samples in a frame has the advantage that in the
23 decoder a simpler decoding becomes possible, which can be
24 carried out in real time and which produces only a slight
25 signal delay. As a result of this sequence it is no longer
26 necessary to first store all the information in the third frame
27 portion in a memory in the decoder. Upon arrival of the encoded
28 digital signal the allocation information is stored in a memory
29 in the decoder. Information content of the allocation

1 information is much smaller than the information content of the
2 samples in the third frame portion, so that a substantially
3 smaller store capacity is needed than in the case that all the
4 samples would have to be stored in the decoder. Immediately
5 upon arrival of the serial data stream of the quantized samples
6 in the third frame portion this data stream can be divided into
7 the various samples having the number of bits specified by the
8 allocation information, so that no previous storage of the
9 signal information is necessary.

10 The allocation information may be in the form of 4-bit
11 words and the scale factor information may be in the form of 6-
12 bit words. The scale factor information is also inserted in the
13 third frame portion before the samples, so that it is possible
14 that during reception the scale factors derived from said scale
15 information are first stored in a memory and the samples are
16 multiplied immediately upon arrival, i.e. without a time delay,
17 by the values of said scale factors.

18 Moreover, it is evident that if after quantisation in
19 the transmitter the subband signal in a subband is zero, which
20 obviously will be apparent from the allocation information for
21 the subband, no scale factor information for this subband need
22 to be transmitted.

23 The inventive steps may be applied to
24 decoders to be used in digital transmission systems, for
25 example systems for the transmission of digital audio signals
26 (digital audio broadcast) via the ether. However, other uses
27 are also conceivable. An example of this is a transmission via
28 optical or magnetic media. Optical-media transmissions may be,
29 for example, transmissions via glass fibres or by means of
30 optical discs or tapes. Magnetic-media transmissions are

1 possible, for example, by means of a magnetic disc or a
2 magnetic tape. The encoded digital signal is then stored in the
3 format as described in one or more tracks of a record carrier,
4 such as an optical or magnetic disc or a magnetic tape.

5 The versatility and flexibility of the decoder thus
6 resides in the special format with which the information in the
7 form of the encoded digital signal is transmitted, for example
8 via a record carrier. The decoder extracts said system
9 information from the data stream and employs it for a correct
10 decoding.

11 The information packets constitute a kind of
12 fictitious units, which are used to define the length of a
13 frame. This means that they need not be explicitly discernible
14 in the information stream of the encoded digital signal.
15 Moreover, the relationship of the information packets with the
16 existing digital audio interface standard is as defined in the
17 IEC standard no. 958. This standard as normally applied to
18 consumer products defines frames containing one sample of both
19 the left-hand and the right-hand channel of a stereo signal.
20 These samples are represented by means of 16-bit two's
21 complement words. If $N = 32$ is selected, one frame of this
22 digital audio interface standard can transmit exactly one
23 information packet of the second digital signal. In the digital
24 audio interface standard the frame rate is equal to the sample
25 rate. For the present purpose the frame rate should be selected
26 to be equal to BR/N . This enables the present ICs employed in
27 standard digital audio interface equipment to be used...-
